EMERGING INFECTIOUS DISEASES

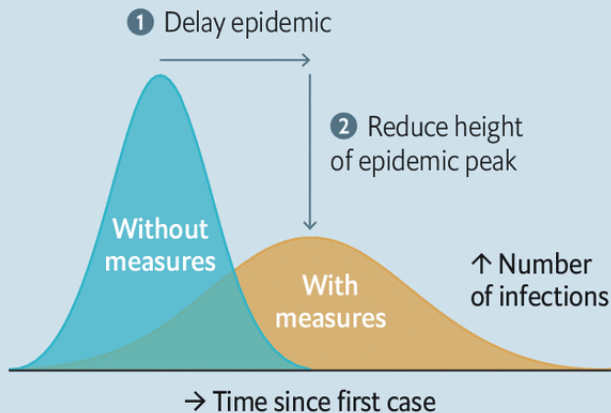

A Peer-Reviewed Journal Tracking and Analyzing Disease Trends

Today...

“Flattening the curve”

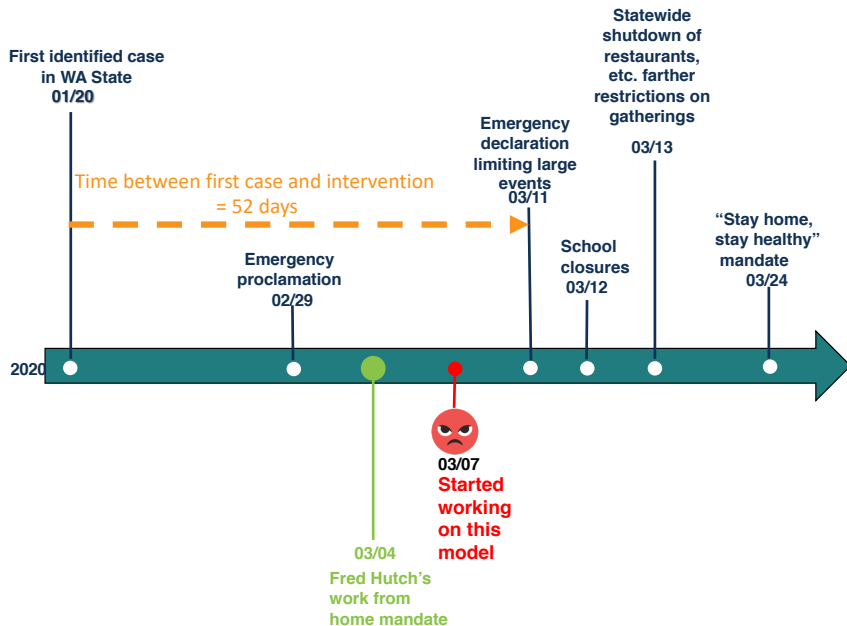

Intended impact of social distancing measures

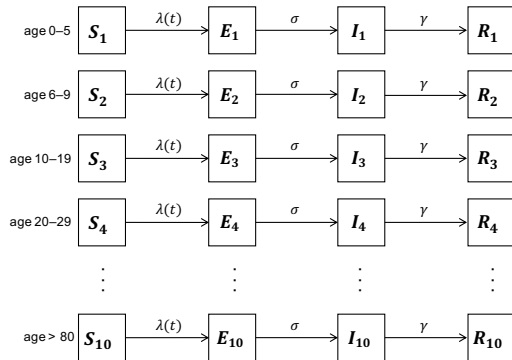

Source: Centres for Disease Control and Prevention

- Started by the CDC
- There was no quantitative analysis of what “flattening the curve” actually meant.

Timeline of events in WA state

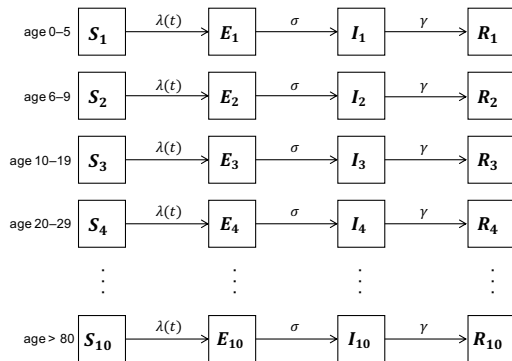

Mathematical model

- Deterministic mathematical model with 10 age groups.
- Contacts depend on the age-groups.
- Age-distribution was calibrated to Seattle metropolitan area.

Mathematical model

For $i = 1 \dots 10$,

$$\frac{dS_i}{dt} = -\lambda S_i,$$

$$\frac{dE_i}{dt} = \lambda S_i - \sigma E_i,$$

$$\frac{dI_i}{dt} = \sigma E_i - \gamma I_i,$$

$$\frac{dR_i}{dt} = \gamma I_i$$

with $\lambda = \sum_{j=1}^{10} \beta \frac{c_{ij}}{N_j} I_j$,

and c_{ij} corresponds to the estimated number of contacts per day between age class i and j in a total population size N .

Important parameters

Parameter	Meaning	Value	Range
$1/\sigma$	Mean latent period	5.16 d	4.5-5.8
R_0	Reproduction number	2.26	1.6-3
$1/\gamma$	Mean infectious period	5.02 d	3-9
β	Infection rate	Calculated	-

Other important assumptions

- We assumed that 20% of the cases would be observed (or ascertained).
- We assumed that mild and severe cases are equally infectious.
- Case fatality rates would be similar to those seen in China.
- Hospitalization rates would be similar to those seen in China.

Scientific questions considered:

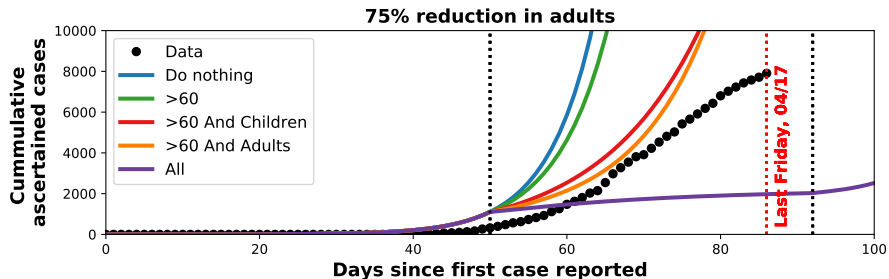

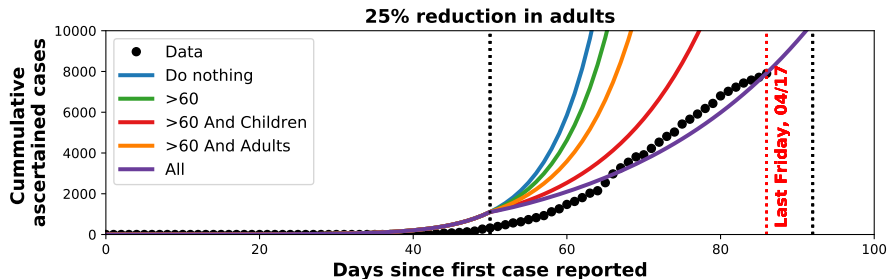

When is the intervention started relative to the epidemic?

- Early on, before the exponential phase: day 50 after first case identified.
- Later, during the exponential phase: day 80 after first case is identified.

Who is reducing their contact rates?

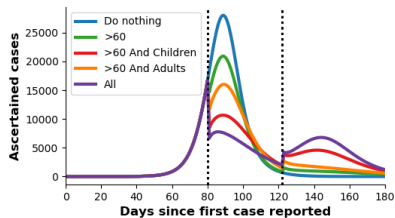

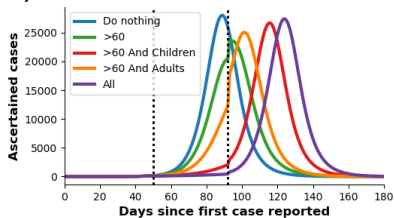

- *Do nothing*: No intervention.
- ≥ 60 : contacts of adults over 60 yo are reduced by 95%,
- ≥ 60 and *Children*: contacts of adults over 60 yo are reduced by 95% and contacts of children are reduced by 85%,
- ≥ 60 and *Adults*: contacts of adults over 60 yo are reduced by 95% and contacts of adults under 60 yo by 25, 75, or 95%
- *All*: contacts of adults over 60 yo are reduced by 95%, contacts of children are reduced by 85%, and contacts of adults under 60 yo by 25, 75, or 95%.

How well does the model do?

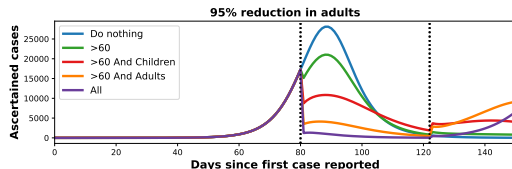

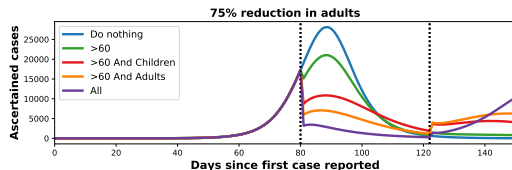

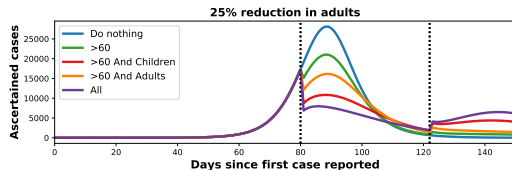

When the intervention is started matters:

A) 25% red in adults < 60

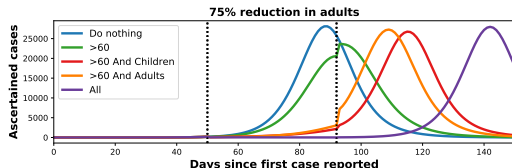

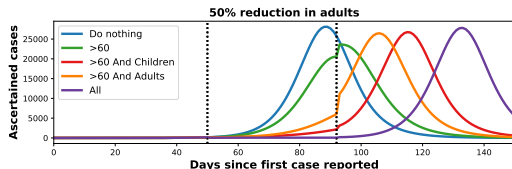

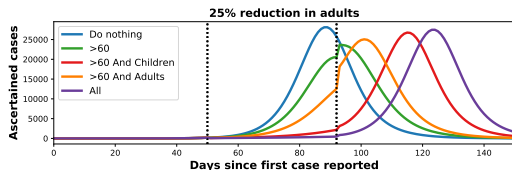

- If started early, it delays the epidemic, irrespective of which intervention is considered.
- If started late, it actually “flattens the curve”.

Flattening the curve: starting during the exponential phase of the epidemic

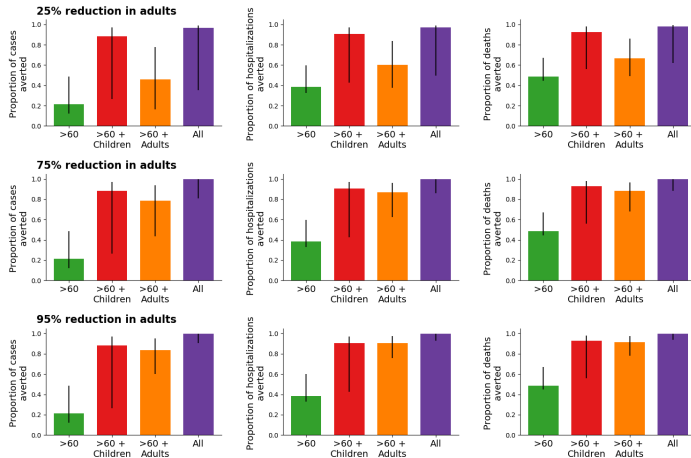

- All strategies flatten the curve, irrespective of proportion of contacts reduced in younger adults.
- There is a rebound for all strategies except for the ≥ 60 strategy.
- The rebound is bigger as adults reduce contacts more.
- For the All strategy there is a 68% - 92% less cases at the epidemic peak.

In a city like Seattle...

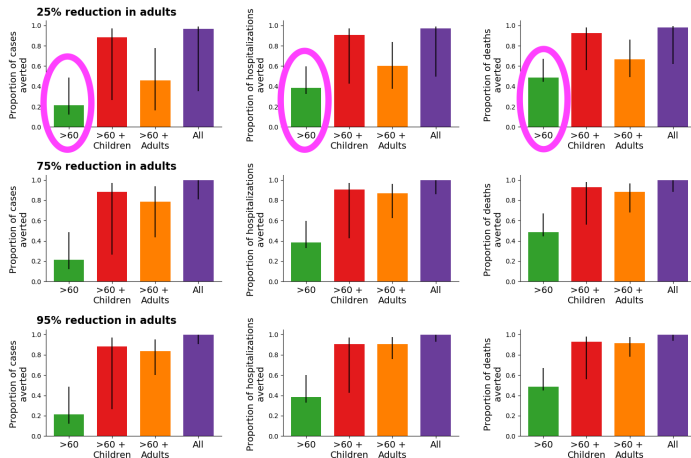

- Assume interventions start on day 50
- All interventions result in delaying the epidemic, regardless of proportion of contacts reduced in younger adults.
- The strategy ≥ 60 delays the epidemic the shortest, by ~ 1 week.
- The strategy $\geq 60 + \text{Children}$ delays the epidemic more than the ones with adults only.
- The strategy *All* delays the epidemic the longest, by 50 days.
- The highest the reduction in contacts in adults, the longest the epidemic is delayed for the $\geq 60 + \text{adults}$ strategy.

How effective are these interventions over the first 100 days

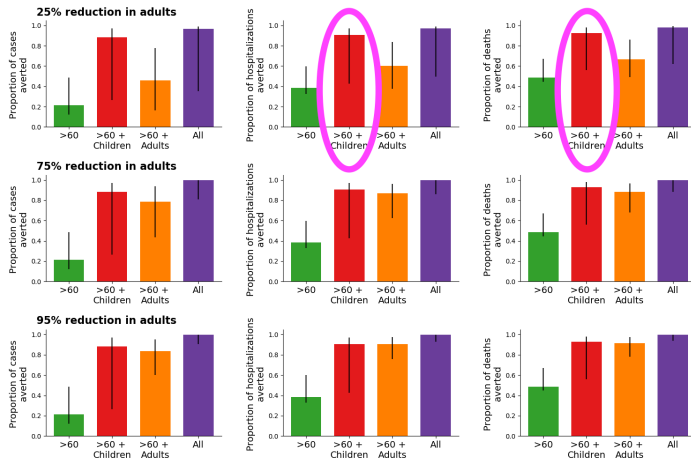

How effective are these interventions over the first 100 days

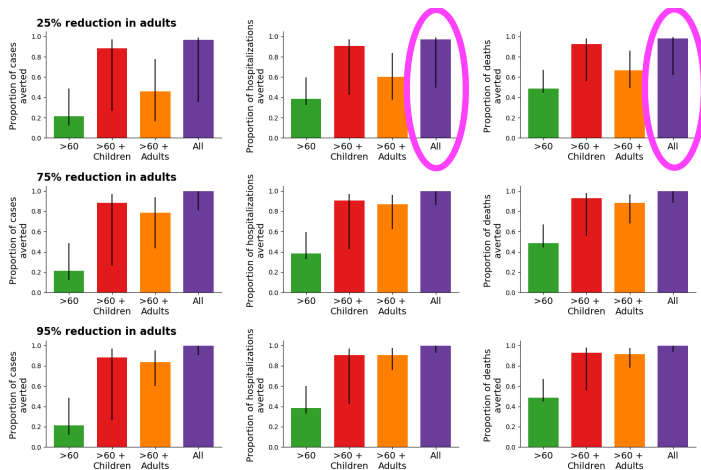

- The strategy ≥ 60 averts 36% hospitalizations and 47% of deaths.

How effective are these interventions over the first 100 days

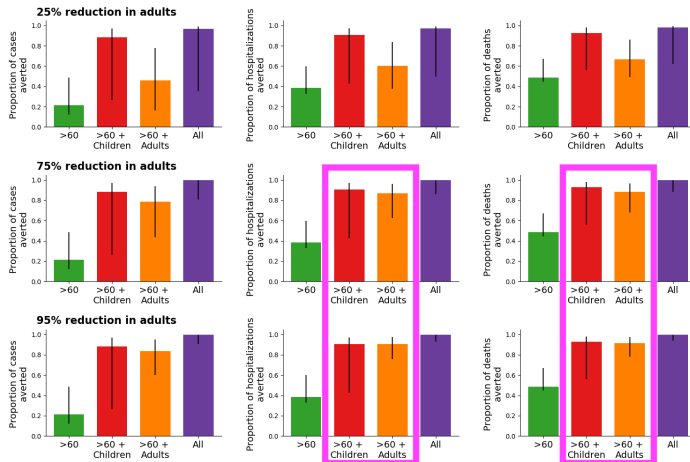

- The strategy $\geq 60 + \text{Children}$ further averts 75% hospitalizations and 80% of deaths.

How effective are these interventions over the first 100 days

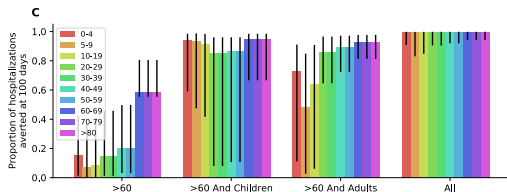

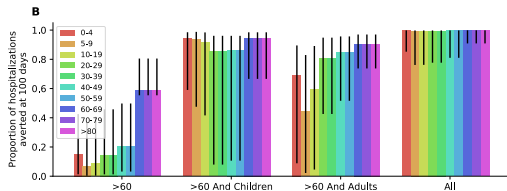

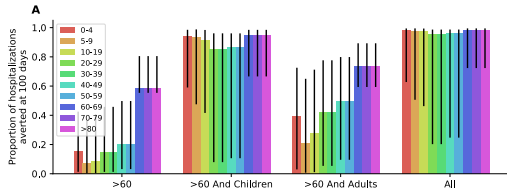

- The strategy *All* averts over 90% of hospitalizations and deaths even with 25% reduction in contacts in younger adults.

How effective are these interventions over the first 100 days

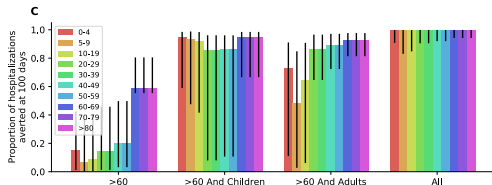

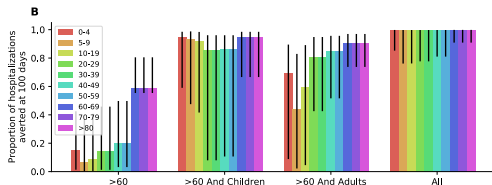

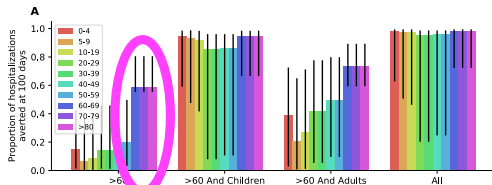

- The strategy $\geq 60 + \text{adults}$ averts as many hospitalizations and deaths as $\geq 60 + \text{Children}$.

Who is getting the most out of these interventions?

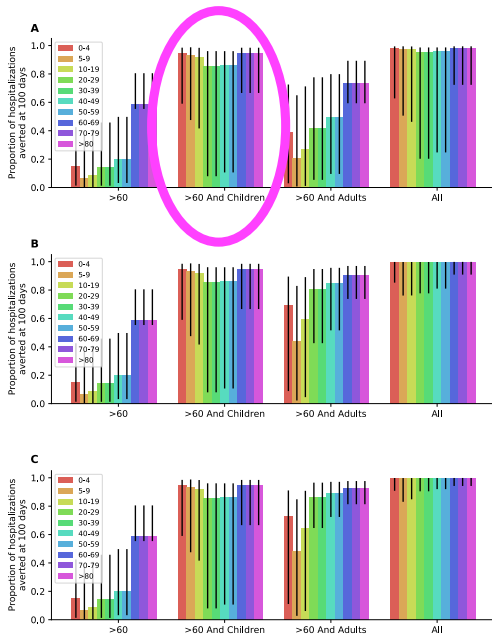

Who is getting the most out of these interventions?

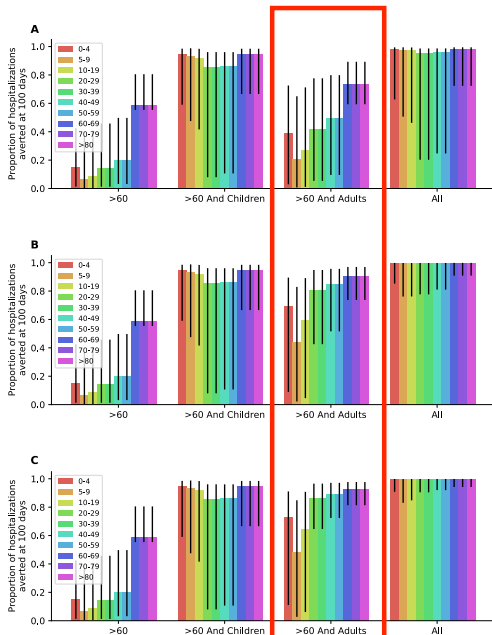

- The strategy ≥ 60 is protecting the older adults the most.

Who is getting the most out of these interventions?

- The strategy $\geq 60 + \text{Children}$ is protecting all age groups roughly equally.

Who is getting the most out of these interventions?

- The strategy $\geq 60 + \text{adults}$ is protecting younger and older adults mostly.
- As more contacts are reduced, a higher percentage of the adult hospitalizations is averted.

Timing of the intervention

- The timing of the social distancing intervention is crucial:
 - Early on → Delay the epidemic.
 - Once in the exponential phase → Flatten the curve.

Which intervention works best?

- Reducing everyone's contacts can avert over 90% of hospitalizations, even when younger adults reduce their contacts by only 25%.
- Reducing older adults contacts only averts $\geq 30\%$ of hospitalizations and deaths (probably not enough not to overwhelm the health system).
- Children are an important part of the chain of transmission.
- ALL INTERVENTIONS are set to rebound if we lift the social distancing interventions.

Other thoughts

- There is a lot of uncertainty around key parameters, and that can affect widely the results (eg proportion of cases ascertained, duration of infectiousness, etc).
- We will have to be very creative to reopen the economy.
- Well-done Seroprevalence studies are a must.
